Statuatory Declaration

I declare that I have developed and written the enclosed work completely by myself, and have not used sources or means without declaration in the text. Any thoughts from others or literal quotations are clearly marked. This Master Thesis was not used in the same or in a similar version to achieve an academic degree nor has it been published elsewhere.

Widmung

Ich widme diese Arbeit meinen beiden liebenvollen Eltern, die den verlorenen Sohn nach 11 Jahren in Wien wie selbstverständlich wieder mit offenen Armen zu Hause in Vorarlberg aufgenommen haben und ihm so ein entspanntes Masterstudium ermöglichten und ihm dadurch halfen ein völlig neues Kapitel in seinem Leben aufzuschlagen.

Abstract

In the paper of [BSV13] a model for endogenous leverage in a continuous double-auction is introduced and it is shown under which circumstances holdings and trading prices approach an equilibrium. One main criteria is the trading network the agents use where Breuer et al. examine only two topologies and report that the prices come to an equilibrium only in the case of a fully connected network. They leave the question open on how the model behaves with different kind of networks and which network topology exactly allows an equilibrium to be reached for further research. This thesis builds upon this model and gives a hypothesis for a necessary condition a network must satisfy to allow the model to approach an equilibrium. Then a few network-topologies are examined in regard of their ability to allow equilibria to be reached or not through computer-driven simulation. As will be shown in this thesis through validation by computer-driven simulation the hypothesis turns out to be correct only after extending the simulation-model by an additional market. This result raises questions this thesis tries to answer about market-mechanisms and market-types when agents don't trade in a fully informed network.

Chapter 1

Introduction

TODO: überarbeiten, passt so noch nicht In 2008 the so called "Subprime Mortgage Crisis" struck the world. It was caused by declining house prices which rose during the US Housing Market Bubble in 2006 to an all-time high. Borrowers used their asset as collateral for the mortgage which constantly increased in value which guaranteed them a low payment-rate because the rate was coupled to the value of the asset. Banks granted "subprime" mortgages to more and more highly risky borrowers. In 2007 borrowers started to default which led to falling prices as the banks reclaimed the collateral and wanted to sell it again on the market to compensate for the loss. This led to a flood of assets which led to a decline of housing prices overall. As the prices fell dramatically the payment-rates rose dramatically to compensate for the cheaper asset. This in turn resulted in even more borrowers going default which resulted in a dramatic downward spiral. Even worse the banks were selling these collateralized products between each other and even insured themselves against defaults of borrowers which led to an even more dramatic kick-back.

This mechanism of borrowing money to buy goods which in turn act as a security for the borrowed money is called leverage which was determined as the primary driving force behind systemic risk in the aftermath of the "Subprime Mortgage Crisis". See Chapter 2.1 "Leverage and Systemic Risk" for a more in-depth discussion.

Up until 2010 leverage was always exogenous in the literature on collateralized credit but recently Geanakoplos and Zame (TODO: cite) proposed theories which endogenized leverage within a general equilibrium framework.

[BSV13] developed a simulation on top of the model of Geanakoplos in which zero-intelligence agents trade assets and loans in a continuous double auction. They wanted to better understand the dynamic of such a theoretical

process and how prices develop instead of being predicted through an equilibrium theory. They TODO: zitierne "ask whether the competitive theory of trade in leveraged assets has descriptive and predictive power in a double auction environment."

4 contributions: 1. double auctions for leveraged assets is new 2. details of institutional specification matter a lot 3. limits of the endogenous leverage model 4.

They could show that in their simulation trading prices and wealth-distribution approach the theoretical equilibrium of Geanakoplos. In their simulation only a fully connected network and a hub-network of agents was investigated where the equilibrium was only reached in the case of the fully connected network. See Chapter 3. "The Leverage Cycle" for a thorough description of the simulation-model of [BSV13].

This thesis investigates more topologies of networks and their states of equilibrium. Furthermore it presents a hypothesis about the necessary property a topology of a network must satisfy to reach the theoretical equilibrium predicted in the theory of Geanakoplos. Interestingly it is shown experimentally that the hypothesis alone does not guarantee the reach of the theoretical equilibrium but further mechanisms needs to be implemented. See Chapter 4 "Hypothesis" and Chapter 6 "Results" for an in-depth explanation of both the hypothesis and why it does not hold and needs to be extended by means of an additional market-mechanism.

For experimental investigation a software was built for this thesis which implemented the exact simulation model of [BSV13] but extended it further to be applicable to arbitrary topologies. See Chapter 5 "Implementation" on details of the software.

In Chapter ?? "Theory" the theoretical background involved with this thesis is presented. First Leverage and systemic risk and its implications are discussed. Then an introduction into the mechanics of Continuous Double Auction as market-mechanisms and equilibrium theory in economics is given. Finally an overview of abstract networks, network-generating algorithms and and their properties is given.

In Chapter 3 "The Leverage Cycle" the theoretical model [BSV13] built their simulation upon is discussed in-depth.

In Chapter 4 "Hypothesis" all topologies which are investigated are introduced and the conjecture about the type of topology necessary to reach the theoretical equilibrium is presented and discussed whether the given topologies could ever approach it or not.

Chapter 5 "Implementation" gives an in-depth explanation of the implementation of the computer-driven simulation presented in [BSV13] including a description of the architecture, implementation of the markets and trading mechanisms.

Chapter 6 "Results" shows the results of simulations of all implemented topologies.

Chapter 7 "Interpretation and Discussions" connects the content of the previous chapters to show that the initial hypothesis of Chapter 4 does not satisfy the equilibrium and shows how it can be reached by introducing an additional market. Then results of simulations with this market are given and discussed where will be shown that using the additional market an equilibrium will be reached but that it is different from the theoretical predictions.

In Chapter 8 "Conclusions" a short sum-up of the thesis and questions left for further research are presented.

2.1 Systemic risk and Leverage

Both are tightly coupled in a way that leverage increases systemic risk dramatically as was the case in the "Subprime Mortgage Crisis".

Systemic Risk

WIKI: It refers to the risks imposed by interlinkages and interdependencies in a system or market, where the failure of a single entity or cluster of entities can cause a cascading failure, which could potentially bankrupt or bring down the entire system or market.

[Bor10]

Leverage

WIKI: In finance, leverage (sometimes referred to as gearing in the United Kingdom and Australia) is any technique to multiply gains and losses.

Accounting Leverage Notational Leverage Economic Leverage

2.2 Continuous Double Auction

Results

In this Chapter the results of the experiments are given. Each topology-type introduced in appendix A was simulated where in this chapter only fully-connected and Ascending-Connected topologies are handled as the Ascending-Connected topology - both without and with importance sampling - is the most minimal network which satisfies the requirements for the hypothesis. The results for the other topologies can be found in appendix B.

Note: The numbers in tables resemble always a median-value with the standard-deviation given in parentheses.

6.1 Replicating theoretical equilibrium

As a point-of-reference and as an experimental proof for the correctness of the implementation of the simulation the results of a replication of the theoretical equilibrium and the equilibrium found in [BSV13] are given. Because equilibrium differs across the number of agents and the type of loan traded to be comparable the same amount of agents and the same loan-type has to be used in the experiments which is 1000 Agents and a 0.5 loan because [BSV13] report their equilibria only for a count of 1000 Agents and loans between 0.1 to 0.5.

6.2 Experiments configuration

In the following experiments 100 Agents were used, all markets (Asset/Cash, Loan/Cash, Asset/Loan) were enabled, as loan-type 0.5 was selected and the number of replications run was 50. A replication was terminated after 1000 failed transactions in a row. Note that if trading is not possible any more before 1000 failed transactions have been reached in a row, the simulation is halted and thus it is possible that it terminates earlier as can be seen for the Ascending-Connected Importance Sampling topology.

[BSV13] showed that equilibrium can be reached already with 30 agents so this was the minimum number of agents to start with but for a smoother visual result 100 were chosen. Also one simulation-run takes not too much time with 100 as compared to the 1000 agents thus it is a very good match between visual accurateness and processing-power requirements.

The 0.5 loan was selected because its a risky one which is important as riskless loans (facevalue $j=0.2$) the results are indifferent and wont show the characteristic progression.

Obviously the whole simulation-process is a random-process with an equilibrium (different for each topology) as the fixed-point solution thus one needs replications to reduce noise. The number of 50 replications was chosen because it is a good match between processing-power requirements and overall reduction of noise - increasing the number e.g. to 100 or 200 would not result in much better results but would need much longer to run. All facts can be seen and derived when using 50 replications thus for all figures 50 replications were used unless stated otherwise e.g. a single run.

Table 5: Configuration for all experiments

TODO: difference to theoretical equilibrium
TODO: use same tables as in "a new market" and use statistical tests after this is solved for "a new market"

Chapter 7

Interpretation

In this chapter interpretation of the results of Chapter 6 "Results" are given and discussed where the central question is whether the ascending-connected topology satisfies the hypothesis or not. Thus only the Ascending-Connected topology is handled - both with and without importance sampling - because it is the most minimal network which satisfies the requirements for the hypothesis. The Hub-, Scale-Free and Small-World Topologies are handled in appendix C as they turn out to fall far from satisfying the hypothesis because almost all of them do not satisfy the requirements for the hypothesis. Special treatment is given to Erdos-Renyi and Watts-Strogatz as they satisfy the hypothesis when using specific parameters for their generating algorithms.

7.1 Validating the Hypothesis

When looking at the results of ascending-connected topology with and without importance sampling from Chapter 6 "Results" of figure 4 and 3 and comparing it with the results of the fully-connected topology of figure 2 it becomes immediately clear that the equilibrium is different from the equilibrium of the fully-connected network and thus theoretical equilibrium is not reached in the case of ascending-connected topology neither with or without importance sampling. Although the visual results come quite close to the fully-connected one - there is a clear distinction between pessimists, medianists and optimists and the wealth-distribution looks about the same as in fully-connected - there remain artefacts in the range of the pessimists. Thus the hypothesis is proven wrong by experiment.

7.2 Analysing artefacts

Obviously the artefacts in the range of the pessimists indicate a miss-allocation of wealth, which are in fact collateralized assets. Pessimists, as noted in Chapter 3 "The Leverage Cycle", are maximally short on assets and bonds and hold only cash, thus it is clearly a miss-allocation. As will be shown it comes from the fact that the pessimists want to sell but no neighbour is able to buy any more - a scenario which is not possible in fully-connected topology and is thus unique to ascending-connected networks with or without importance sampling.

7.2.1 Dynamics of a single run

To better understand how such artefacts arise one needs to investigate the dynamics of a single run of ascending-connected topology.

Figure 5: Wealth-Distribution of Ascending-Connected topology after a single run

The wealth stabilizes from both the left and the right end of the optimism-scale towards the i1-point where medianists become optimists - around this point the last trades will happen.

Pessimists try to sell all their assets against cash to the neighbour with higher optimism-factor.

Optimists try to buy as much assets as they can get from the neighbour with lower optimism-factor. In the beginning they use cash and after they've ran out of cash they buy assets against bonds.

The medianists serve as connection between the pessimists and optimists, serving in transferring the assets to the optimists by buying from lower op-

timism and selling to higher ones either through asset against cash or asset against bond.

Thus the assets move from the pessimists through the ascending chain of optimism to the optimists as no direct connection between these two groups exists with the medianists in between. Thus waves of uncollateralized assets can be seen moving from pessimists to optimists.

It is important to understand that all agents despite their optimism factor make offers on all markets if they are able to, e.g. cash, collateral or bond constraints satisfied. This implies that pessimists trade bonds as well as assets against bonds - the agents are not defined exogenous as pessimists/medianist/optimists but this property is emerges during the simulation.

Thus pessimists gain wealth in collateralized assets which can be seen by the green spikes with the same amount of negative bonds as those assets are bought against bond - see Chapter ???. Of course they try to sell it to neighbours with higher optimism factor but this is only possible if these neighbours are able to buy which they can if they hold enough bonds to buy the offered asset for the offered amount of bonds.

Whether an agent has enough wealth to buy from a seller is more or less random and depends on its trading history. Matching happens randomly and thus it is possible that the neighbourhood of a seller "dries up" as the potential buyers sold all their good to the next agent with higher optimism factor and become thus unable to buy from the potential seller because they have no more bonds to buy assets against bonds. In such a case a potential pessimist seller of collateralized assets is then cut from its environment and becomes unable to trade any more resulting in a miss-allocation in collateralized assets.

It is also possible for a group of agents to get cut from its environment through this random trading-process. In this case this "island" of agents still trades between each other resulting in the uncollateralizing of assets which immediately are traded towards optimists but as soon as a point is reached where no buyer is available with enough bonds to buy collateralized assets this island is also incapable of trading any more resulting in an island of miss-allocated wealth.

An important fact to notice is that the artefacts must not necessarily show up. It is possible for a single run to finish without these artefacts showing up. This is due to the random-process of sweeping and matching and thus the artefacts are subject to this random process too. Importance sampling elevates this problem a bit as it allows for more trades as the matching

probabilities are very much increased but fails in the end for the same reason as the simulation without it - the artefacts are just "smaller" but show up almost always.

7.3 Extending the Hypothesis

After it has become clear that the hypothesis is wrong the question arises what needs to be done to correct it. It is clear that a mechanism needs to be found which prevents or resolves the arising of the artefacts within the pessimist wealth-range. Obviously two solutions are available.

7.3.1 Approaching fully connectedness

Increasing the connectedness of the topology increases the probability of global-optimal trades and allows more agents to trade between each other and thus the probability of resolving islands or artefacts of wealth miss-allocation is increased with the density of connectedness. The experiments of ascending-connected topology with short-cuts were designed to get an understanding how the simulation behaves with increasing connectedness and also how the two types fully and regular of connectedness influence the results. It seems that full shortcuts seem to help dramatically although the number of full shortcuts seem to be dependent on the number of agents. TODO: verweis auf results und interpretation appendix

Of course in real environments approaching fully connectedness is not always possible and thus only the other mechanism is left as an option to resolve the artefacts.

7.3.2 Re-Enabling trading

Another way to look at the arising of the artefacts is because of suboptimal trades. [BSV13] were confronted with this circumstance when they introduced the "Asset against Bond" Market where they found that the equilibrium was fundamentally different from theoretical one because agents were trapped in suboptimal trades and couldn't reverse their decisions made earlier. As a solution they introduced the "Bonds-Pledgeability" (BP) mechanism which allows to trade bonds in both ways instead of only gathering them and not being able to sell them - see ?? for a more in-depth discussion of the BP-Mechanism.

Thus if those artifacts are treated as suboptimal trades one needs to introduce a mechanism similar to BP to allow the reversibility of suboptimal

trades in the context of collateralized assets. The only possibility without altering the network-topology is to re-enable the pessimists to trade their collateralized assets against cash as all pessimists hold cash and are thus able to buy and sell collateralized assets against cash. This new mechanism is expected to repair the miss-allocated wealth and to restore the validity of the previously disproved hypothesis.

See Chapter ?? "A new Market" for the implementation and results of this new mechanism.

Chapter 8

A new Market

As already introduced in chapter ?? "Interpretation" a new market is necessary to repair the miss-allocation of collateralized assets in the range of the pessimist agents by enabling the agents to trade collateralized assets against cash.

8.1 Implementation

8.1.1 Price-Range

As for all other 3 Markets the price-ranges of the offers must be defined. Note that all prices must obviously be in the unit of cash.

minimum When calculating the minimum price of a collateralized asset - that is how much is the collateralized asset minimally worth - it is important to include the collateral-aspect of the asset. Thus one starts with the minimum asset-price in cash which is the down-price pD and subtracts the maximum possible amount of cash which is bound through a bond as collateral which is the face-value V . This value is a constant for all agents.

$$\min \text{ collateralized asset-price} = \min(0, pD - V)$$

maximum To calculate the maximum price of a collateralized asset - that is how much is the collateralized asset maximally worth - one needs to include the collateral-aspect of the asset too. Equal to calculating the minimum one starts now with the maximum asset-price in cash which is the up-price pU and subtracts the minimum possible amount of cash which is bound through a bond as collateral which is the face-value pD . This value is a constant for all agents.

$$\max \text{ collateralized asset-price} = pU - pD$$

limit Applying the same rules as in minimum and maximum to the limit price calculation one needs to subtract the limit-price of loans from the limit-price of asset to receive the limit-price of a collateralized asset. This value is individual for each agent as the limit-prices differ across the agents both for assets and loans.

$$\text{limit-price of collateralized asset} = \text{limit-price of asset} - \text{limit-price of loan}$$

8.1.2 Bid-Offering

The way bid-offers are generated is very similar to the "Bond against Cash" market. Bid Offerings are generated only when the agent has any cash holdings. The price is drawn randomly between the minimum price and the limit-price because when buying one wants to buy below the expected value to make a profit. As amount one TRADING-UNIT of an asset is selected - in the thesis-implementation 0.1 - but if there is not enough cash left to buy one TRADING-UNIT of assets then the amount of assets is selected which can be bought with the remaining cash holdings.

Table 13: Bid-Offering parameters

Pre-Condition	$\text{cash holdings} > 0$
Asset-Price	$\text{random}(\min \text{ coll. asset-price}, \text{limit-price of coll. asset})$
Asset-Amount	$\min\left(\frac{\text{cash holdings}}{\text{Asset-Price}}, \text{TRADING-UNIT}\right)$

8.1.3 Ask-Offering

The way ask-offers are generated is very similar to the "Bond against Cash" market. Ask Offerings are generated only when the agent has any collateralized assets. The price is drawn randomly between the limit-price and maximum price because when selling one wants to sell above the expected value to make a profit. As amount one TRADING-UNIT of an asset is selected - in the thesis-implementation 0.1 - but if there are fewer collateralized assets left then the remaining amount of collateral is selected.

See Chapter ?? "Implementation" for the equation of collateral holdings.

Table 14: Ask-Offering parameters

Pre-Condition	$\text{collateral holdings} > 0$
Asset-Price	$\text{random}(\text{limit-price of coll. asset}, \text{max coll. asset-price})$
Asset-Amount	$\min(\text{collateral holdings}, \text{TRADING-UNIT})$

8.1.4 Match

Below the wealth-exchange table is given in case of a match between two agents on the new market.

Table 15: Wealth-Exchange on match

	Seller	Buyer
Loan Given	+ matching-amount	N/A
Loans Taken	N/A	- matching-amount
Assets holdings	- matching-amount	+ matching-amount
Cash holdings	+ matching-price	- matching-price

8.2 Results

Of most importance are the results of the simulation when using the new market. The plain results are given in this section where the interpretation of the results are given in the following section.

As experiment-configuration the same is used as given in Chapter 6 "Results" except that the new market is now activated too.

8.2.1 Fully-Connected topology

8.3 Interpretation of results

Interpreting the results the following questions must be answered:

- Does the Fully-Connected topology reach the theoretical equilibrium as well?
- Does the new market repair the miss-allocation of wealth in the pessimists-range?
- If not why? If yes, does the Ascending-Connected topology approach theoretical equilibrium now?

Does the Fully-Connected topology reach the theoretical equilibrium as well? Yes it does. Both visual and statistical results show that it reaches the theoretical equilibrium. The medianist wealth is slightly higher with the new market but that difference, as well as the variations in the other variables are not statistically significant. TODO: genauer.

Does the new market repair the miss-allocation of wealth in the pessimists-range? Yes it does. The visual results are clear: no more miss-allocations show up within 50 replications.

If yes, does the Ascending-Connected topology approach theoretical equilibrium now? No it does not. Both visual and statistical results show that it misses to reach the theoretical and fully-connected topology with/without new market equilibrium: genauer. Clearly the visual and statistical results are different than in the case without the new market but that was expected and is a necessity if the new market repairs the miss-allocation of wealth in the pessimists-range. TODO: genauer.

8.4 Simulation and Market dynamics

When implementing a new market the market-dynamics are of very importance and thus the following questions must be answered.

- How does trading progress with this new market? Is it the same as without the new market?
- How does the new market resolve the miss-allocation (turning on after no more possible)?
- When and how much is each market active?
- Can the trading stages 1-4 be identified too as given in [?]?
- How do the market-activities change when a new market is introduced?

To answer these questions one must look closely at the market-dynamics. There are trading stages but due to the new market or the different topology they are quite different from the ones found in [?]. The method used to find these stages is observation of many single runs and refining the observations over and over again. Replications provide no real value here as one needs to look very carefully into the dynamics of single runs instead of the mean of multiple runs.

8.4.1 Fully-Connected with new Market

8.4.2 Ascending-Connected without new Market

3 Stages were identified where all of them can be seen in the Market-Dynamics diagram.

Figure 8: Market-activity stages of Ascending-Connected topology without collateral/cash market

Stage 1 The allocations are very chaotic overall but pessimists can be identified already as they sell their free assets against cash thus holding primarily cash but lots of collateralized assets are in the pessimists-range as well. Real distinction of optimists is not yet visible and medianists are far from showing up.

The asset/cash and loan/cash markets are very dominant in this stage as the pessimists try to get cash for their free assets where the asset/loan market is hardly active but contributes enough to create the miss-allocation of the collateralized assets in the pessimists-range already.

Figure 9: Wealth-Distribution of Ascending-Connected topology without collateral/cash market during Stage 1

Stage 2 The pessimists which hold collateralized assets try to trade them up to the optimists which looks like waves when visualizing it in the thesis-software. The optimists are now about to emerge as most of them are maximally short on cash and hold either free or collateralized assets. The medianists are still not visible yet.

The asset/cash market seems to go down in the long term while the loan/cash and asset/loan markets seems to increase as the fewer assets can be traded against cash and the optimists are already very low on cash thus the asset/loan market is naturally increasing.

Figure 10: Wealth-Distribution of Ascending-Connected topology without collateral/cash market during Stage 2

Stage 3 The pessimists lie dormant and are completely inactive. The medianists begin to show up holding only bonds and the real optimists begin

to cristalize holding only collateralized assets. These two frontiers move towards each other and when they have reached, trading is over and SOME equilibrium is reached

The asset/cash market lies dormant as well as because the pessimists are no more able to trade without the new market and the optimists are maximally low on cash. The loan/cash market is inactive too whereas the asset/loan market takes over and dominates 100% as only collateralized assets are traded on asset/loan market.

Figure 11: Wealth-Distribution of Ascending-Connected topology without collateral/cash market during Stage 3

8.4.3 Ascending-Connected with new Market enabled after 1000 successive failed Transactions

Using the thesis-software it is possible to start a simulation-run on ascending-connected topology without the collateral/cash market and enabling it after 1000 successive failed transactions which gives interesting hints about how the spikes of collateralized assets in the pessimists-range are resolved and distributed over the already existing pure optimists.

Of course there are the same 3 Stages to be found as above whereas the deferred enabling of the collateral/cash market adds 2 new Stages.

Figure 12: Market-activity stages of Ascending-Connected topology with deferred activated collateral/cash market

Stage 4 The collateralized assets are traded against cash and sum up at the i0-point where the first agent has no more cash.

Figure 13: Wealth-Distribution of Ascending-Connected topology with deferred activated collateral/cash market during Stage 4

Stage 5 Now the asset/loan market becomes 100% dominant again and the collateralized assets are traded through the medianists towards the pure optimists as they have no more cash and can only trade anymore on this remaining active market.

Figure 14: Wealth-Distribution of Ascending-Connected topology with deferred activated collateral/cash market during Stage 5

8.4.4 Ascending-Connected with new Market

4 Stages were identified where only 3 of them can be seen in the Market-Dynamics diagram.

Figure 15: Market-activity stages of Ascending-Connected topology with collateral/cash market

Stage 1 Pessimists and optimists begin to emerge where the pessimists are gathering cash and collateralized assets and the optimists are gathering free assets against cash and a few collateralized assets. There are no medianists visible yet.

The asset/cash market and loan/cash market start around 40% slightly decreasing where the collateral/cash market starts around 10% with increasing tendency. The asset/loan market is makes 2% of the total activity. It is clear to see that the collateral/cash market is increasing as the amount of collateralized assets which moves towards the optimists increases.

Figure 16: Wealth-Distribution of Ascending-Connected topology with collateral/cash market during Stage 1

Stage 2 In the pessimist-range large amount of collateralized assets have gathered which are traded now towards the optimists as the pessimists try to get maximally short on any assets and maximally plus on cash. Those collateralized assets are traded towards the i0-point - that is the first agent who holds no more cash - which can be seen by a spike in the wealth-distribution of figure 17 around 0.65. There are no medianists visible yet.

The collateral/cash market raises above the asset/cash and loan/cash markets and either fluctuates or stays quite constant. In figure 15 the fluctuating variant is shown. If the market fluctuates the asset/cash and loan/cash fluctuate inverse in that if collateral/cash market raises they go down and vice versa. If the collateral/cash market stays quite constant in this stage it raises above 90% and asset/cash and loan/cash markets decline to 0%. Why the collateral/cash market either fluctuates or stays constant is not clear but is most probably dependent on the allocation of collateralized assets in the pessimists-range. The asset/loan market becomes a bit more active as more collateralized assets are traded.

Figure 17: Wealth-Distribution of Ascending-Connected topology with collateral/cash market during Stage 2

Stage 3 Pessimists are now final and won't change any more. Optimists-range is now clearly visible and holds a large amount of collateralized assets from the pessimists which needs now to be traded and distributed to the remaining optimists. Medianists are still not visible yet.

Because the pessimists are no more able to trade and the optimists hold no more cash the activity of the collateral/cash market drops rapidly and asset/loan market raises to 100% activity as only collateralized-assets are tradeable any more.

Figure 18: Wealth-Distribution of Ascending-Connected topology with collateral/cash market during Stage 3

Stage 4 Medianists begin to show up and to distinguish themselves from the pure optimists. This is no more visible on the market-dynamics as only asset/bonds are traded anymore.

Figure 19: Wealth-Distribution of Ascending-Connected topology with collateral/cash market during Stage 4

How does trading progress with this new market? Is it the same as without the new market? TODO. vermutung: gleich, aber es wird halt auch noch der neue markt verwendet

How does the new market resolve the miss-allocation? TODO nocheinmal die dynamiken untersuchen: wie passiert schlussendlich das unkollateralisieren von assets? die kollateralisierten assets werden ja nicht unkollateralisiert sondern wandern einfach zu den optimisten. unkollateralisiert werden sie ja nicht. die medianisten haben keinen cash mehr und kaufen assets gegen bonds und unkollateralisieren sie. genau erklären.

Can the trading stages 1-4 be identified too as given in [?]?

8.5 Conclusions on new Market

The equilibrium of the ascending-connected topology with the new market is different than the fully-connected one which reaches the theoretical equilibrium. Thus the hypothesis is still wrong because it predicted the ascending-connected topology to reach the theoretical equilibrium. This thesis can only speculate on the real reason for this but the reason is most probably rooted in the fundamental different trading dynamics of ascending-connected topology compared to fully-connected as can be seen in the market-dynamics. This thesis leaves this question open for further research.

Medianist Wealth	3.713 (0.125)
Optimist Wealth	5.0 (0.0)

Table 60: Performance of Ascending-Connected 30 regular short-cuts topology

Successful TX	5427.02 (90.82)
Total TX	6566.06 (96.04)
Failed TX	1139.04 (27.74)

B.3 Hub-Based topologies

The Hub-Based Topologies fail to come even close to equilibrium due to reasons given in Chapter "Topologies and Hypothesis". This can be seen also very clearly in the visual results and thus no performance- and equilibrium-tables are listed as they would not make any sense.

B.3.1 3-Hubs

Figure 45: Wealth-Distribution of 3-Hubs topology

B.3.2 1-Median Hub

Figure 46: Wealth-Distribution of 1 Median-Hub topology

B.3.3 3-Median Hubs

Figure 47: Wealth-Distribution of 3 Median-Hubs topology

B.3.4 Maximum Hub

Figure 48: Wealth-Distribution of Maximum-Hub topology

B.4 Scale-Free and Small-World topologies

This topologies fail to come even close to equilibrium too due to reasons given in Chapter "Topologies and Hypothesis". This can be seen also very clearly in the visual results and thus no performance- and equilibrium-tables are listed as they would not make any sense.

B.4.1 Erdos-Renyi

Figure 49: Wealth-Distribution of Erdos-Renyi 0.2 topology

need to show network too because random ?

APPENDIX B. VISUAL RESULTS FOR HUB-BASED, SCALE-FREE AND SMALL-WORLD

Figure 50: Wealth-Distribution of Erdos-Renyi 0.1 topology

need to show network too because random ?

Figure 51: Wealth-Distribution of Erdos-Renyi 0.05 topology

need to show network too because random ?

B.4.2 Barabasi-Albert

Figure 52: Wealth-Distribution of Barabasi-Albert $m_0=3$, $m=1$ topology

need to show network too because random ?

Figure 53: Wealth-Distribution of Barabasi-Albert $m_0=9$, $m=3$ topology

need to show network too because random ?

B.4.3 Watts-Strogatz

Figure 54: Wealth-Distribution of Watts-Strogatz $k=2$, $b=0.2$ topology

need to show network too because random ?

Appendix C

Interpretation of results of Hub-, Scale-Free and Small-World Topologies

C.1 Hub Topologies

C.1.1 3-Hubs

C.1.2 1-Median Hub

C.1.3 3-Median Hubs

C.1.4 Maximum Hub

C.2 Scale-Free and Small-World topologies

C.2.1 Erdos-Renyi

todo: kann hypothese erfüllen mit entsprechender parameterisierung

C.2.2 Barbasi-Albert

C.2.3 Watts-Strogatz

todo: kann hypothese erfüllen mit entsprechender parameterisierung
